ABSTRACT

It is well accepted that C, crops have increased growth, biomass, and yield under enriched CO_2 environment. However, only small responses to CO_2 enrichment are observed for C_4 crops. The magnitude of the effect of CO_2 enrichment on crops is not well known yet due to experimental differences among the various CO2 enrichment studies. So far, only few studies were carried out under field conditions with full season CO2 exposure. In order to better estimate the impact of future atmospheric CO₂ increases, on grain yields, on C₃ and C₄ crops, field studies were conducted using open-top chambers to mimic atmospheric CO2 concentrations that are predicted to occur during the first half of the coming century (500 ppm CO₂) The experiments were conducted at USDA Beltsville Agricultural Research Center with soybeans (Glycine Max; C, crop) during 1989 and 1990, with wheat (Triticium aestivum; C3 crop) during 1991 and 1992; and with corn (Zea mays; C4 crop) during 1991. Crops were grown under CO₂ concentrations of ambient (350 ppm CO₂) or +150 ppm CO₂, during 12 h day', from early growth until physiological maturity. The impact of CO₂ enrichment on soybeans grain yield was not significant in either 1989 (~+10%, p=0.42) or 1990 (~+8%, p=0.37) However, CO, enrichment had a significant impact on wheat grain, increasing grain yield by ~12% (p<0.05) when combined over years. Corn grain yield was unchanged under CO₂ enrichment. The results indicated that CO₂ enrichment had a physiological beneficial effect in wheat and soybeans (C, crops) but not in corn (C, crop), however, future changes in atmospheric CO2 concentrations may be escorted by other factors such as rising temperature, sir pollution, and diseases, that are likely to have a negative impact on agricultural production.
